Abstract. We examine what we regard as key observational results on GRB 970228 and GRB 970508 and show that the accumulated evidence strongly suggests that γ-ray bursts (GRBs) are cosmological fireballs.

We further show that the observations suggest that GRBs are not associated with the nuclear activity of active galactic nuclei, and that late-type galaxies are more prolific producers of GRBs.

We suggest that GRBs can be used to trace the cosmic history of the star-formation rate. Finally, we show that the GRB locations with respect to the star-forming regions in their host galaxies and the total burst energies can be used to distinguish between different theoretical models for GRBs.

INTRODUCTION

It is very often the case in astronomy that multiwavelength observations of a single object allow a dramatic progress in the understanding of the object, and γ-ray bursts (see e.g. Fishman and Meegan, 1995) proved to be no exception. The identification of the X-ray and optical counterparts of the two γ-ray burst sources GRB 970228 and GRB 970508 marks a remarkable milestone in the research of these enigmatic objects (e.g. Costa et al. 1997 a,b; Heise et al. 1997; Piro et al. 1997; van Paradijs et al. 1997; Sahu et al. 1997 a,b; Bond 1997; Djorgovski et al. 1997; and references therein). In the present short note, we first present what we regard as the key findings and their potential implications, and we then examine possibilities to make further progress with regard to specific γ-ray burst models.

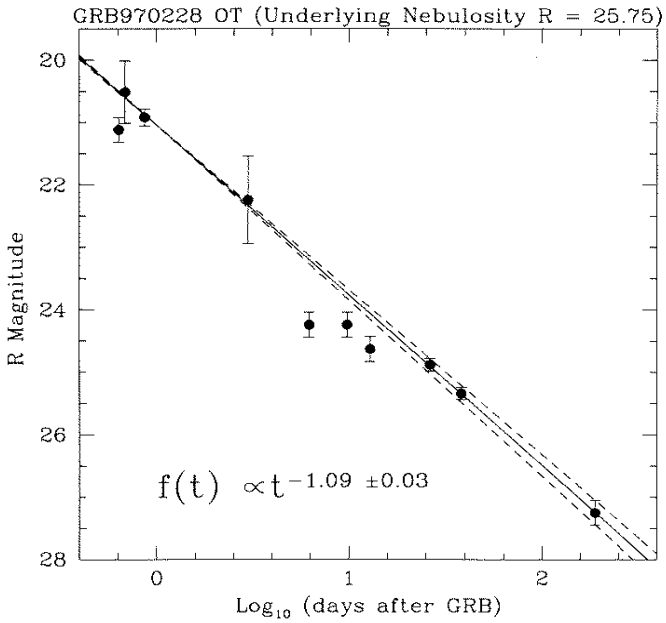

FIGURE 1. The decay behavior of the optical transient associated with GRB 970228 in R-band.

KEY OBSERVATIONAL RESULTS AND THEIR MAIN IMPLICATIONS

We regard the following observational findings (in no particular order) as providing the main clues for the understanding of the nature of γ-ray bursts:

(1) Contrary to claims made by Caraveo et al. (1997 a,b), *no significant proper motion has been detected for GRB 970228* (the limit is 36 milliarcsec per year, Sahu et al. 1997 a,b; Fruchter et al. 1998). This makes an extremely close origin for the GRB very unlikely.

(2)*An absorption- and emission-line system at z=0.835 has been detected in the optical spectrum of GRB 970508* (Metzger et al. 1997 a,b).

Since this absorption/emission system probably arises from a host (or intervening) galaxy, this provides direct evidence that this GRB is at a cosmological distance (assuming, of course, that the identification of the source is correct).

(3) The principal features of the afterglow in the optical (see Fig. 1) are well represented by a forward-radiating blast-wave model (Mészáros and Rees 1997). In fact, given the fact that the afterglows may be expected to depend on the properties of the environment of the GRB and on the angular anisotropy of the fireball itself (e.g. Mészáros, Rees and Wijers 1997), the agreement with the simplest model can be considered quite remarkable.

(4) *No break towards a more rapid decline has been seen so far in the power-law behavior of the light curve (Fig. 1).* Such a break is expected to occur after

the blastwave has 'snowploughed' through a rest-mass energy of the order of the burst energy, since the remnant then becomes nonrelativistic (e.g. Wijers, Rees and Mészáros 1997). The timescale for such a break to occur is given by

$$t_{break} \simeq \left(\frac{3E_\gamma}{4\pi\rho c^5}\right)^{1/3} = \begin{cases} 1yr \left(\frac{E_\gamma}{10^{51}erg}\right)^{1/3} \left(\frac{n}{0.1cm^{-3}}\right)^{1/3} \\ 2days \left(\frac{E_\gamma}{10^{42}erg}\right)^{1/3} \left(\frac{n}{0.001cm^{-3}}\right)^{1/3} \end{cases} \quad (1)$$

where ρ is the medium density (n is the number density), E_γ is the burst energy, and we have scaled these quantities with values appropriate for a cosmological or extended halo origin, respectively. Eq. (1) clearly demonstrates that the fact that a break has not yet been observed in GRB 970228, more than six months after the burst, strongly favors a cosmological origin.

(5) *A potential host galaxy has been identified in the case of GRB 970228* (Sahu et al. 1997a; Fruchter et al. 1998; see Fig. 2). The probability of a chance superposition of the source with a galaxy of that magnitude (V $\sim$ 25.7) is of the order of 2% (Fruchter et al. 1997a).

An examination of points (1) -(5) above clearly suggests that GRBs are cosmological fireballs. While it is certainly true, that with only two optical afterglows observed so far, an alternative explanation can be found for each one of the above points (e.g. the host galaxy of GRB 970228 could be a chance superposition afterall; what is thought to be the counterpart of GRB 970508 may be an unrelated BL Lac object, etc.), the combined weight of all the observational facts strongly argues against a local origin for the GRBs. We will therefore from here on *assume* that GRBs are cosmological, and that GRB 970228 is indeed located in what appears to be its host galaxy.

GENERAL IMPLICATIONS AND SPECIFIC MODELS FOR GRBS

A close examination of the HST images of GRB 970228 (Sahu et al. 1997a; Fruchter et al. 1997a) reveals two more observational facts:

(i) The GRB is not at the center of the host galaxy.

(ii) The galaxy looks like a dwarf irregular or spiral, not like an elliptical galaxy.

The first of these facts implies that *GRBs are probably not associated with the central massive black holes in their host galaxies*, or in general, with the nuclear activity of active galactic nuclei. This rules out, for example, tidal disruption of stars (Carter, 1992) as potential models for GRBs. The second point is somewhat less certain, because the faintness of the galaxy makes any morphological determination not entirely conclusive. Nevertheless, taken at face value, this observation suggests that the frequency of GRBs may be *higher in late-type galaxies*. This, in turn, favors models for GRBs which involve a young stellar population. Leading models in this category include: merging neutron stars (e.g. Eichler et al. 1989) or

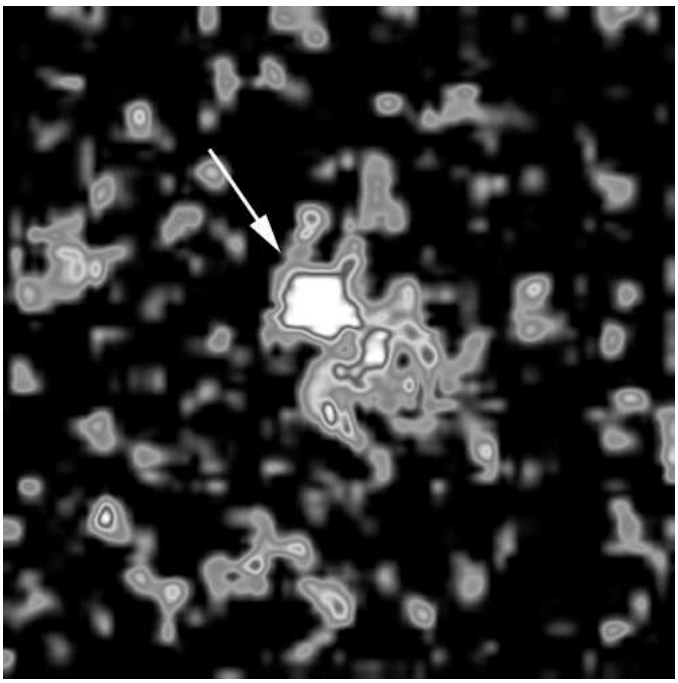

FIGURE 2. Smoothed HST image of GRB 970228, taken in March/April 1997 with the WFPC2 camera (Sahu et al. 1997a).

a neutron star and a black hole (e.g. Mochkovitch et al. 1993), "failed type Ib supernovae" (Woosley 1993), "hypernovae" (Paczyński 1997a), radio pulsar glitches (Melia and Fatuzzo 1992) and, to a lesser extent, collapsing white dwarfs (Usov 1992). For example, Sahu et al (1997a) have shown that the ratio of the neutron-star merger rate in disk galaxies to that in ellipticals is about 80 (see also Phinney 1991; Narayan, Piran and Shemi 1991).

Another important thing to realize is the fact that *all* the leading models for GRBs have relatively short delays ($\leq 10^9$ yr) with respect to the star formation process. Consequently, *GRBs essentially trace the redshift distribution of the star-formation rate* (Sahu et al. 1997b; Totani 1997; Wijers et al. 1997). This means that one can use the inferred cosmic history of the star-formation rate (Madau et al. 1996; Connolly et al. 1997) to construct a synthetic log N - log P relation for GRBs. Turned around, given enough statistics, the redshift distribution of GRBs can provide *an independent test* for the cosmic history of the star formation rate.

Finally, we can ask: is the available data sufficient to point us towards a specific model for the GRBs?

There are at present two pieces of information which can, in principle, provide clues in this direction. One is related to the burst energy and the other to the burst location (see also Pazyński 1997b). In Table 1, we list some of the most popular GRB models, the total energy expected from these models, and the expected location of the GRBs with respect to the birth place of their progenitors. One

TABLE 1. Locations of GRBs and Total Energies in Different Models.

Model	Location of GRB	Total Energy (ergs)
Failed supernova	In star-forming region	$\sim 10^{51}$
Hypernova	In star-forming region	$\sim 10^{54}$
White-dwarf collapse	In disks or globular clusters	$\sim 10^{51}$
Merging neutron stars or neutron star+BH	Up to tens of kpc away from the star-forming region	$\sim 10^{51}$

should note that failed supernovae (Woosley 1993), hypernovae (Paczyński 1997a) and white dwarf collapses (Usov 1992) are all expected to be found near the birth place of their progenitors for the following reasons. Since failed supernovae and hypernovae originate from very massive stars, the lifetime of their progenitors is short, $\sim 10^6$ yrs, and consequently, they cannot travel very far. The progenitor lifetime of a white dwarf collapse can be longer, but its space velocity is typically low. On the other hand, double neutron star systems are expected to be born with high kick velocities of the order of a few hundred km s^{-1} (Lyne and Lorimer 1994; White and van Paradijs 1996; Fryer and Kalogera 1997), and it takes them typically a long time ($\sim 10^8$ yr) to merge. Consequently, the GRBs in this case can be expected to be found typically 30 kpc away from their birthplace. Unfortunately, the existing data do not provide yet a clear picture concerning the burst locations. For example, while the detection of the [OII] 3728Å emission line (Metzger et al 1997b) in GRB 970508 seems to indicate the presence of a relatively dense medium (and thus, a potential association with a star-forming region), HST failed so far to detect a host galaxy at the burst location (Fruchter et al. 1997b), while two nearby faint galaxies (which could, in principle, be the hosts) were detected at distances of ∼30 kpc and 35 kpc (for z=0.835, $H_0 = 65$ km s^{-1} Mpc^{-1}). Similarly, the location of GRB 970228 near the edge of its host galaxy does not give us conclusive information on whether the progenitor has moved from its birth place or not.

Concerning the total energy, again the present data are still very inconclusive. For example, the total energy inferred for GRB 970508 was $\sim 10^{52}$ ergs, assuming spherical emission (Waxman 1997a,b). The situation is further complicated by the possibility that the γ-ray emission is beamed (e.g. Wijers et al. 1997b).

In spite of the difficulties pointed out above, the burst locations and the total energies do hold the potential of providing in the future the next step from generic fireballs to specific physical models.
